Supporting Information

ABSTRACT: α -Aminoradicals undergo halogen atom abstraction to form halomethyl radicals in reactions initiated by the combination of *tert*-butyl hydroperoxide, aliphatic trialkylamine, halocarbon, and copper(I) iodide. The formation of the α -aminoradical circumvents preferential hydrogen atom transfer in favor of halogen atom transfer, thereby releasing the halomethyl radical for addition to alkenes. The resulting radical addition products add the *tert*-butylperoxy group to form α -peroxy- β,β -dichloropropylbenzene products that are convertible to their corresponding β,β -dichloro-alcohols and to novel pyridine derivatives. Computational analysis clearly explains the deviation from traditional HAT of chloroform and also establishes formal oxidative addition/reductive elimination as the lowest energy pathway.

INTRODUCTION

Radical addition reactions of alkenes with dissociable molecular species ($X-Y$) provide convenient access to vicinal disubstituted products with increased molecular and functional complexity (Figure 1a). The initiation of these reactions effects atom transfer that forms radical Y , which adds to the carbon-carbon double bond to form a carbon radical that abstracts X from $X-Y$ to enter the catalytic cycle. In one of the most

notable examples of these reactions, Kharasch et al. reported in 1945 the acetyl peroxide-induced Markovnikov addition of Cl and CCl_3 from CCl_4 to alkenes.¹ The Kharasch reaction has been extensively investigated,^{2,3} and numerous examples of atom-transfer radical addition using transition-metal catalysts to initiate CCl_3 radical generation have been reported.^{4–7} However, when this process was applied with chloroform (Figure 1b), the initiation step generated the CCl_3 radical by H-atom transfer (HAT), rather than forming the dichloromethyl radical by chlorine-atom transfer.¹ In fact, the dichloromethyl radical can be generated by a HAT from CH_2Cl_2 ,⁸ albeit indirectly via an aryl radical formed from a boronic acid or an aryldiazonium salt, and a catalytic methodology has been reported to utilize the chloroform analogue $CHCl_2Br$ in the presence of stoichiometric amounts of tri- and tetra-tertiary amines as an alternative.⁹ Transition-metal compounds, especially those of low valent platinum,¹⁰ are well-known to undergo oxidative addition with halocarbon solvents, but there has not been a report of a catalytic process through which the dichloromethyl radical has been generated from chloroform. We wish to report an effective indirect methodology for preferential chlorine-atom abstraction from chloroform and its application to the regioselective addition of $CHCl_2$ and the *tert*-butylperoxy radical to styrenes, resulting in α -peroxy- β,β -dichloropropylbenzene products in moderate-to-high yields (Figure 1c), and their conversion to the corresponding β,β -dichloro-alcohols and novel pyridine

derivatives. Experimental data along with density functional theory (DFT) calculations demonstrate the essential role of the α -aminoradical that changes the preference of atom extraction from CHCl_3 . An excellent correlation that is found to be valuable for selecting appropriate radical and a general mechanism are also proposed.

RESULTS AND DISCUSSION

We envisioned that generation of the dichloromethyl radical from chloroform would be a function of the relative energies for C–Cl versus C–H homolytic bond cleavage from various radical initiators. Those atom-transfer agents that have been reported ($t\text{BuOO}\cdot$, $t\text{BuO}\cdot$, $\text{OH}\cdot$, and $\text{Ar}\cdot$) favor C–H bond cleavage,^{8a,11} but this list is limited.¹² As shown in Scheme 1,

Scheme 1. Different Polar Effects of Atom-Transfer Reaction

we expected that reversing radical polarity would lead to free radical species that could favor C–Cl bond cleavage and thereby provide a viable pathway for the generation of halogenated carbon radicals.

A search for appropriate radicals was initiated with examining adiabatic ionization potentials (IPs) of carbon radicals.¹³ The calculated IPs and differences in free energy barriers of hydrogen-atom transfer (HAT) versus chlorine-atom transfer (CAT) ($\Delta G_{\text{H}}^\ddagger - \Delta G_{\text{Cl}}^\ddagger$) are listed in Table 1 and plotted in Figure 2.

Indeed, the IPs indicate the potential of releasing an electron and a good correlation between IP and the preference of HAT versus CAT was found. Results in Table 1 and Figure 2 suggested that α -amino radicals would favor C–Cl homolytic cleavage to generate the dichloromethyl radical.¹⁴ More specifically, α -amino radicals were indicated to have the highest potential to undergo chlorine-atom abstraction with energy differences greater than those of α -alkoxy carbon radicals (Table 1, entries 1–6). Alkyl, α -carbonyl, and phenyl radicals, in contrast, have a higher preference for C–H bond homolytic cleavage (Table 1, entries 7–9).

On this basis, we searched for those reactants that preferentially form an intermediate radical capable of undergoing chlorine-atom abstraction from chloroform to produce the CHCl_2 radical.¹⁵ Tertiary amines were surveyed, but with the caveat that generation of α -amino radicals is subject to the oxidation potential of the amine. Specifically, electron transfer (ET) is the initial step in the catalytic oxidation of N,N -dialkylanilines to their corresponding iminium ions by *tert*-butyl hydroperoxide (TBHP),¹⁶ whereas hydrogen atom transfer (HAT) occurs preferentially as the initial step in the similar oxidation of tetrahydroquinolines.¹⁷

Because of their demonstrated suitability for free radical addition reactions, styrenes were selected as the target substrates.¹⁸ Reactions were performed in various solvents containing excess chloroform, amines capable of HAT, and selected catalysts known to form the *tert*-butylperoxy radical. Table 2 provides an abbreviated selection of various screening parameters (see Supporting Information for full screening

parameters). As expected, trialkylamine bases performed well under the reaction conditions in the presence of $\text{Rh}_2(\text{cap})_4$ (Table 2, entries 1–3). When 3° benzylamines and anilines were used, no conversion of the styrene reactant to product was observed (Table 2, entries 4 and 5). $\text{Rh}_2(\text{OAc})_4$ was ineffective at room temperature or 65°C , and silver-based catalysts showed moderate product formation (Table 2, entries 7 and 8). However, use of CuI gave nearly quantitative formation of the desired product (Table 2, entry 9). No significant drop in yield was observed at ambient temperature,

^aReaction conditions: unless indicated otherwise, the reaction of **1a** (1.0 mmol), catalyst (1 mol %), TBHP (5.0 equiv), and amine (5.0 equiv) was carried out in CHCl₃ (5.0 mL) at 65 °C. ^bIsolated yield. ^cCHCl₃:acetone were used in a 1:1 ratio as cosolvents (5.0 mL) at rt.

although the low solubility of CuI in organic solvents led to inconsistent initiation/yields. To overcome this problem, we used acetone as a cosolvent, and this change provided high reproducibility to these reactions (Table 2, entry 10). Furthermore, screening of the amine and the copper catalyst showed that the DIPEA and CuI provide the best result (Table 2, entries 11–16). No product could be detected without both 3° aliphatic amine and CuI (Table 2, entries 17 and 18, and Supporting Information).¹⁸

The optimum catalyst, amine, and reaction conditions were applied to substituted styrenes, and the results obtained showed generality for this transformation (Scheme 2). Styrenes with both electron-rich and electron-deficient substituents at the *para*-, *meta*-, and *ortho*-positions of the phenyl moiety furnished product in moderate-to-high yields (2a–2k). Furthermore, substitution at the α -position of styrene also gave product with good yields (2l–2m), and 1-vinylnaphthalene and 2-vinylnaphthalene were also compatible with this catalytic process (2n–2o). In reactions with vicinal disubstituted alkenes, however, an additional 3.0 equiv of TBHP were necessary to obtain higher yields (2p–2q). Cumyl peroxide was also compatible under the reaction conditions (2r). However, di-*tert*-butylperoxide (DTBP) and benzoyl peroxide were unreactive.

Other perhalogenated compounds that could undergo hydrogen-atom abstraction were also found to be selective for halogen-atom abstraction (Table 3, except entries 1, 5, and 6). Several methodologies undergo similar addition of alkyl halides but oftentimes are limited to substrates wherein α -halogens are excluded.¹⁹ Under our standard reaction conditions where mixed halogenated compounds were used, selectivity for I > Br > Cl > F removal was observed (Table 3,

^aReaction conditions: Unless indicated otherwise, the reaction of **1** (1.0 mmol), R–X (5.0 equiv), CuI (1 mol %), TBHP (5.0 equiv), and DIPEA (5.0 equiv) was carried out in acetone (5.0 mL) at rt. ^bIsolated yields.

entries 1–3) in moderate-to-high yields. Carbonyl substrates containing α -halogenated esters also underwent addition in good yields (Table 3, entries 4 and 5). Finally, while reactivity remained high for chloroform derivatives and bromoform (Table 3, entry 7) and for chlorine-atom transfer from tetrachloromethane (Table 3, entry 6), iodoform (Table 3, entry 8) consistently led to lower conversions, possibly because of subsequent reactions.

Moreover, the dichloromethyl addition reaction could be carried out on a gram scale with high product yield using only 0.025 mol % CuI (eq 1). Considering that the reaction does

not give **2a** without the CuI catalyst (Table 2, entry 17), we conclude that CuI is very efficient but also essential. Furthermore, without the 3° aliphatic amine the reaction takes an entirely different course.

The synthetic utility of the peroxide products was studied next.²⁰ Different from “Russell mechanism” where the alcohol is a derived in a 1:1 mixture with their corresponding carbonyl

Scheme 2. Substrate Scope of Alkenes for Dichloromethyl Radical Addition^a

^aReaction conditions: Unless indicated otherwise, reactions of **1** (1.0 mmol), CuI (1 mol %), TBHP (5.0 equiv), and DIPEA (5.0 equiv) were carried out in CHCl_3 /acetone (1:1, 5.0 mL) at rt. ^bAfter 30 min, an additional 3.0 equiv of TBHP were added. ^cCumyl hydroperoxide was used as an alternative to TBHP , and an additional 3.0 equiv of cumyl hydroperoxide were added after 30 min.

products,²¹ the peroxide products can be easily converted to their alcohol counterparts by a rarely applied reduction that occurs in acetic acid with zinc dust (Scheme 3).²² In all cases,

Scheme 3. Transformation of Peroxide Products to Benzyl Alcohols

^aAfter 48 h an additional 3.0 equiv of Zn dust was added. ^bAfter 48 h, an additional 5.0 equiv of Zn dust was added. ^cProduct yield includes 10% acetate ester.

once starting material was consumed, a simple basic aqueous workup led to the desired product with no need for additional purification. For the *para*-methoxyphenyl substrate, the main product was the alcohol **4d**, but 10% of acylated **4d'** was also isolated.

Another example of the utility of the dichloromethyl addition process is evident in the conversion of the addition products to substituted pyridine derivatives, a recent example of which is a palladium-catalyzed condensation of acetonitrile with homopropargylic alcohols.²³ We were delighted to observe that formation of substituted pyridines occurred in moderate yields in the presence of KO^tBu in acetonitrile

(Scheme 4). A similar process, known as the Thorpe-Ziegler reaction, is used in the self-condensation reactions of aliphatic

Scheme 4. Transformation of Peroxide Products into Substituted Pyridines

nitriles that results in the synthesis of enamines that provide ketone products after acid hydrolysis.²⁴ The X-ray structure of **5b** was obtained for full characterization. A full study of this reaction and its implications is ongoing.

The radical nature of the transformation is suggested by the reaction conditions that have been employed, but additional experimentation confirms this inference (Scheme 5). Reaction

Scheme 5. Mechanistic Experiments To Probe the Radical Pathway

of **1a** under standard reaction conditions along with TEMPO as an additive provided no conversion of the starting material (Scheme 5, eq 1). Additionally, with use of vinylcyclopropane **6** as the substrate to ascertain the fate of the initially formed reaction intermediate and its lifetime, several products were formed in addition to **7a**: ketone **7b** and ring-opening products **7c** and **7c'** (Scheme 5, eq 2). Major product **7a** is consistent with the overall addition process from which products **7c** and **7c'** are formed and whose yields suggest the relative rates for capture by the *tert*-butoxy radical versus ring-opening/hydrogen-atom transfer.²⁵ The formation of cleavage product **7b** is due to the initial addition of the *tert*-butoxy radical to **6**, and its formation in reactions with O_2 or H_2O_2 as the oxidant has been reported.²⁶

From a mechanistic standpoint, the most likely initiation of this reaction is by TBHP and CuI to form the *tert*-butoxy radical by hydrogen-atom transfer from TBHP to the initially formed *tert*-butoxy radical²⁷ (Scheme 6). This process has been extensively studied.²⁸ The Cu^{II} species produced by this oxidative reaction, $(\text{HO})\text{CuI}$, is proposed to be in equilibrium

Scheme 6. Initiation of the Process Leading to the Dichloromethyl Radical through Formation of α -Aminoradical 9

with ICu-OO^tBu (**8**).²⁹ A HAT of the *tert*-butylperoxy radical with the trialkylamine generates the α -aminoradical (**9**) that is the key intermediate which preferentially undergoes chlorine-atom abstraction from chloroform. The CHCl₂ radical generated from chloroform adds regioselectively to the terminal carbon of styrene to generate the benzyl radical.

That the α -aminoradical is the key intermediate is not only inferred from the calculations reported in Table 1 but also its involvement is strongly supported by the direct observation of iminium ion **11** using ¹H NMR spectral analysis under the standard conditions (Scheme 7). Addition of H₂O sequestered

Scheme 7. ¹H NMR Spectral Observation of Iminium Ion **11 and Acetaldehyde **12** in the Standard Reaction**

the intermediate quantitatively to acetaldehyde **12**. The reaction was also monitored by ¹H NMR under the standard reaction conditions, and acetaldehyde was observed to ultimately form in a 1:1 ratio to the peroxide product (see Supporting Information).

Hydrogen-atom abstraction from tertiary amine bases is key to understanding the formation of the dichloromethyl radical from chloroform, and may also contribute to understanding recently published copper(II) hydroxide-catalyzed generation of the dichloromethyl radical from CHCl₂Br whose transformations are dependent on the stoichiometric uses of tertiary amine bases (Scheme 8, eq 1).⁹ The requirement for amines

Scheme 8. Copper-Catalyzed Dichloromethylazidation of Alkene Using CHBrCl₂ or CHCl₃ as the Dichloromethylating Reagent

may also indicate that the amine plays an important role in the generation of the dichloromethyl radical rather than being only a ligand or base. Under our conditions with CuI, TBHP, and DIPEA, reaction with TMS-azide produces the same azide addition product as was reported by Wang and co-workers [in competition with formation of **2a** (Scheme 8, eq 2)]; and increasing the stoichiometric amount of TMSN₃ also increases the yield of the azide **13** relative to **2a** (see Supporting Information); this outcome suggests that the indirect methodology makes possible a broad spectrum of radical oxidative addition processes.

As we were submitting this article for publication, Li and co-workers reported the use of cobalt(II) acetylacetonate as a catalyst and triethylamine as a base for difluoroalkylation-peroxidation of arylalkenes (eq 2).^{15d} In their survey of

applicable halogenation reagents they reported one example using chloroform in which the dichloromethyl product **2h** was formed in 41% yield, and we have confirmed this result. The role of trimethylamine was proposed to be solely that of a base to neutralize acid formation, but the results that we report suggests that the tertiary amine is essential for halogen-atom abstraction.

The selectivity of CAT versus HAT for the generation and oxidative addition of the dichloromethyl radical was subjected to DFT analysis (Scheme 9). Hydrogen-atom abstraction from

Scheme 9. Computed Free Energy Diagram for α -Amino Radical Mediated Reactions with Chloroform^a

^aCalculations were at the B3LYP-D3 level.

the α -position of DIPEA to the *tert*-butylperoxy radical occurs with a relatively low activation barrier of 15.8 kcal/mol. The HAT from chloroform to the DIPEA radical was calculated to have a higher energy barrier (23.5 kcal/mol) than the CAT from chloroform to the DIPEA radical (12.7 kcal/mol). This preference is sufficiently great to direct the reaction exclusively to the dichloromethyl radical.

The formation of peroxide products **2** and **3** in relatively high yields narrows the possible outcomes to three distinct pathways (Scheme 10). In Pathway A a single-electron transfer (SET) by Cu^{II} would yield a benzyl carbocation which could be intercepted by TBHP or, in theory, by other suitable nucleophiles, including water in T-HYDRO. However, when the reaction was conducted in the presence of alternative

Scheme 10. Three Possible Mechanistic Pathways for Product Formation

nucleophiles, no deviation in product selectivity for **2** was observed (i.e., with MeOH, NaOH/H₂O, indole). In Pathway B the formation of **2** occurs through a two-step outer-sphere ligand transfer between ICu-OO^tBu and the benzyl radical. Alternatively, in Pathway C addition of Cu^{II} to the benzyl radical, resulting in Cu^{III} species **14**, followed by reductive elimination regenerates the catalyst and affords the observed product. This pathway has been used to explain other copper-catalyzed addition reactions involving TBHP,³⁰ but there has not been experimental evidence for this pathway, and asymmetric induction from the use of chiral ligands for copper(I) (and, alternatively, for dirhodium(II) carboxamides) offered an attractive experiment that might distinguish this pathway from Pathway B. However, only borderline enantioselectivity was observed in the presence of chiral ligands (see [Supporting Information](#)), possibly because of ineffective metal–ligand coordination. Because the lack of enantioselectivity does not fully discredit this particular pathway, we turned to DFT calculations to further distill the key reaction intermediates as well as which route was more plausible.

The three pathways for C–O bond formation were probed ([Scheme 11](#)). A single-electron transfer to form the benzylic carbocation was calculated to have the highest energy profile (Pathway A) which explains why no product loss due to the presence of other nucleophiles is observed. The direct outer sphere ^tBuOO ligand transfer had the next highest energy barrier (TS4-Dis in Pathway B), whereas the formal oxidative addition of copper to styrene followed by reductive elimination (TS4-Re in Pathway C) was calculated to have the lowest activation free energy for the two steps and, so, is considered to be the most favorable pathway. The Cu–C and O–C distances (2.45 and 2.39 Å) in TS4-Re are much longer than the reported enantioselective cases.³¹ Such ineffective coordination accounts for the experimental observation of the lack of enantioselectivity (see [Supporting Information](#)).

CONCLUSIONS

In conclusion, a previously unrealized chlorine-atom transfer from chloroform was achieved by an indirect process through which catalytic TBHP-induced formation of an α -aminoradical causes chlorine-atom transfer from chloroform, forming the dichloromethyl radical that undergoes regioselective addition to the carbon–carbon double bond of styrenes. This process was optimized to form various substituted α -peroxy- β , β -dichloropropylarene products and was also suitable for

Scheme 11. Computed Free Energy Diagram for C–O Bond Formation^a

^aCalculations were at the B3LYP-D3 level and distances are in Å.

halogen-atom abstraction of additional alkyl halides to form diverse α -peroxy- β -substituted ethylbenzene products. An excellent correlation between IPs and the difference in free energy barrier of HAT versus CAT was found. The correlation provides a general method to select appropriate radical for halogen-atom transfer reaction. Furthermore, the mechanism for halogen-atom transfer involving α -amino radical intermediates unifies disparate reports and establishes a cohesive framework for further advances. A detailed computational investigation clearly demonstrated the deviation from traditional HAT of chloroform and also established a formal oxidative addition/reductive elimination as being the lowest energy pathway. The *tert*-butylperoxide products formed by this methodology are reducible to their corresponding alcohols under mild conditions and are also convertible to highly substituted pyridine derivatives in acetonitrile.
